Research Report n° 7987 — June 2012 — 26 pages

Abstract: A memory model is an important component of the formal semantics of imperative programming languages: it specifies the behavior of operations over memory states, such as reads and writes. The formally verified CompCert C compiler uses a sophisticated memory model that is shared between the semantics of its source language (the CompCert subset of C) and intermediate languages. The algebraic properties of this memory model play an important role in the proofs of semantic preservation for the compiler. The initial design of the CompCert memory model is described in an article by Leroy and Blazy (J. Autom. Reasoning 2008). The present research report describes version 2 of this memory model, improving over the main limitations of version 1. The first improvement is to expose the byte-level, in-memory representation of integers and floats, while preserving desirable opaqueness properties of pointer values. The second improvement is the integration of a fine-grained mechanism of permissions (access rights), which supports more aggressive optimizations over read-only data, and paves the way towards shared-memory, data-race-free concurrency in the style of Appel’s Verified Software Toolchain project.

Le modèle mémoire CompCert version 2

Résumé : Le modèle mémoire est un composant important de la sémantique formelle d’un langage impératif de programmation : il spécifie le comportement des opérations sur les états mémoire, tels que les lectures et les écritures. Le compilateur formellement vérifié CompCert C utilise un modèle mémoire élaboré, qu’il partage entre les sémantiques de son langage source (le sous-ensemble CompCert de C) et de ses langages intermédiaires. Les propriétés algébriques de ce modèle mémoire jouent un rôle important dans les preuves de préservation sémantique du compilateur. La première version du modèle mémoire CompCert est décrit dans un article de Leroy et Blazy (J. Autom. Reasoning 2008). Ce rapport de recherche décrit la version 2 de ce modèle mémoire, qui résout les principales limitations de la version 1. Première amélioration : il expose la représentation en mémoire, au niveau de l’octet, des entiers et des flottants, tout en préservant les propriétés utiles d’opacité des pointeurs. Seconde amélioration : il intègre un mécanisme de permissions (droits d’accès) à grain fin, qui autorise le compilateur à effectuer des optimisations plus agressives sur les données en lecture seule, et constitue un premier pas vers le parallélisme à mémoire partagée bien synchronisé, dans le style du projet Verified Software Toolchain d’Appel.

Mots-clés : Modèles mémoires, sémantiques formelles, compilation vérifiée, CompCert
# Introduction

The imperative programming paradigm views programs as sequences of commands that incrementally update a memory state, also called store. A memory model is a specification of memory states and operations over memory, such as reads and writes. Such a memory model is a prerequisite to giving formal semantics to imperative programming languages, verifying properties of programs, and proving the correctness of program transformations.

For high-level, type-safe languages such as ML or the sequential fragment of Java, the memory model is simple and amounts to a finite map from abstract memory locations to the values they contain. At the other end of the complexity spectrum, we find memory models for shared-memory concurrent programs with data races and relaxed (non sequentially consistent) memory, where much effort is needed to capture the relaxations (e.g., reorderings of reads and writes) that are allowed and those that are guaranteed never to happen [1].

In this work, we focus on memory models for the C programming language and for compiler intermediate languages, in the sequential case but with planned extensions to data race-free concurrency. The C language and the intermediate languages we consider feature both low-level aspects such as pointers, pointer arithmetic, and nested objects, and high-level aspects such as separation and freshness guarantees. For instance, pointer arithmetic can result in aliasing or partial overlap between the memory areas referenced by two pointers; yet, it is guaranteed that the memory areas corresponding to two distinct variables or two successive calls to malloc are disjoint. A very abstract memory model, such as the popular Burstall-Bornat model [7, 6], can fail to account for desirable features of the languages we are interested in, such as casts between incompatible pointer types. A very concrete memory model, such as the hardware view of memory as an array of bytes indexed by addresses that are just machine integers [15], fails to enforce separation and freshness guarantees, and makes it impossible to prove the correctness of standard compiler passes and even of late, link-time or loading-time placement of code and data in memory.

In the context of the CompCert project [11], where we formally verify the correctness of a realistic, optimizing C compiler, we developed and formalized in the Coq proof assistant a memory model for the CompCert C dialect of the C programming language and for the various intermediate languages of the CompCert compiler. Version 1 of the CompCert memory model is described in details in an article by Leroy and Blazy [12] and summarized in section 2. In the years following this publication, several limitations of this “v1” memory model appeared, some related to low-level programming idioms used in embedded systems, others related to the extension of CompCert towards race-free concurrent programming as investigated in the Verified Software Toolchain project of Appel et al [2].

The limitations mentioned above and described in section 3 led us to refine the CompCert memory model in two directions. One is to expose the byte-level machine representation of integers and floating-point numbers, while keeping abstract the machine representation of pointers, as required to preserve crucial invariance properties of invariance by generalized renaming of block identifiers. The other direction is to add fine-grained permissions, also known as access rights, on every byte of the memory state, giving precise control on which memory operations are permitted on these bytes. For instance, the in-memory representation of a C string literal can be given read-only permissions, allowing reads but preventing writes and deallocation.

This new memory model was introduced in release 1.7 of CompCert, then further refined in release 1.11. This technical report documents the CompCert 1.11 memory model, which we call the CompCert memory model version 2.
2 The CompCert memory model, version 1

We first review version 1 of the CompCert memory model, referring the reader to Leroy and Blazy [12] for full details.

In this model, memory states $m$ are collections of blocks, each block being an array of abstract bytes. (See figure 1.) Pointers are represented by pairs $(b, i)$ of a block identifier $b$ and a byte offset $i$ within this block. Each block $b$ has two integer bounds, low\_bound $m$ $b$ and high\_bound $m$ $b$. Valid offsets within block $b$ range between low\_bound $m$ $b$ inclusive and high\_bound $m$ $b$ exclusive. (The size of block $b$ is therefore high\_bound $m$ $b$ − low\_bound $m$ $b$ bytes.)

Our semantics for CompCert C and the Clight intermediate language [4] associate a different block to every global variable of the program, to every addressable local variable of every active invocation of a function of the program, and to every invocation of malloc. For local variables, fresh blocks are allocated at function entry point and deallocated when the function returns.

Pointer arithmetic modifies the offset part of a pointer value, keeping its block identifier part unchanged:

$$(b, i) + n \overset{\text{def}}{=} (b, i + n)$$

As a consequence, blocks are separated by construction: from a pointer to block $b$, no amount of pointer arithmetic can create a pointer to block $b' \neq b$; pointer arithmetic can only create other pointers within block $b$, or illegal pointers outside $b$’s bounds.

As an abstract data type, memory states are presented as a type $\text{mem}$, a constant $\text{empty} : \text{mem}$ denoting the empty memory state, and the 4 operations

$$\begin{align*}
\text{alloc} & : \text{mem} \rightarrow \mathbb{Z} \rightarrow \mathbb{Z} \rightarrow \text{mem} \times \text{block} \\
\text{free} & : \text{mem} \rightarrow \text{block} \rightarrow \text{mem} \\
\text{load} & : \text{mem} \rightarrow \text{memory\_chunk} \rightarrow \text{block} \rightarrow \mathbb{Z} \rightarrow \text{option val} \\
\text{store} & : \text{mem} \rightarrow \text{memory\_chunk} \rightarrow \text{block} \rightarrow \mathbb{Z} \rightarrow \text{val} \rightarrow \text{option mem}
\end{align*}$$

$\text{alloc} m l h$ allocates a fresh block of size $h - l$ bytes, with low bound $l$ and high bound $h$. It returns the updated memory state and the block identifier for the fresh block.

$\text{free} m b$ deallocates the block $b$, returning the updated memory state in which block $b$ has bounds $(0, 0)$ and can therefore no longer be read from or written to.

$\text{store} m \tau b i v$ stores value $v$ with type $\tau$ in block $b$ at offset $i$. Values are the discriminated union of 32-bit machine integers, 64-bit floats, pointer values, and a special $\text{Vundef}$ value denoting an unknown value:

$$v \ ::= \text{Vint}(i) \mid \text{Vfloat}(f) \mid \text{Vptr}(b, i) \mid \text{Vundef}$$

Memory types $\tau$ indicate the size, type and signedness of the value being stored:

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{memory_shape}
\caption{General shape of memory states}
\end{figure}
The CompCert memory model version 2

\[ \tau ::= \text{Mint8signed} \mid \text{Mint8unsigned} \mid \text{Mint16signed} \mid \text{Mint16unsigned} \mid \text{Mint32} \mid \text{Mfloat32} \mid \text{Mfloat64} \]

8-bit integers | 16-bit integers | 32-bit integers or pointers | 32-bit, single-precision floats | 64-bit, double-precision floats

Each type \( \tau \) comes with a size \( |\tau| \) in bytes and a natural alignment \( \langle \tau \rangle \).

As shown by the option mem return type, memory stores can fail because they perform bounds and alignment checking. The store succeeds and returns Some \( m' \) (where \( m' \) is the updated memory state) if and only if bounds and alignment constraints are respected:

\( \langle \tau \rangle \text{ divides } i \land \text{low\_bound } m b \leq i \land i + |\tau| \leq \text{high\_bound } m b \)

Otherwise, store returns None.

load \( m \tau b i \) reads a value of type \( \tau \) from block \( b \) at starting offset \( i \). The load succeeds and returns Some \( v \) (where \( v \) is the value read) if and only if bounds and alignments constraints are respected, as in the case of store. Otherwise, None is returned.

The following “good variable” laws characterize most of the semantics of these 4 memory operations.

Load after alloc: if alloc \( m l h = (m', b) \),

- load \( m' \tau' b' i' = \text{load } m \tau' b' i' \) if \( b' \neq b \)
- If load \( m \tau b i = \text{Some } v \), then \( v = \text{undef} \)

Load after free: if free \( m b = m' \),

- load \( m' \tau' b' i' = \text{load } m \tau' b' i' \) if \( b' \neq b \)
- load \( m \tau b i = \text{None} \).

Load after store: if store \( m \tau b i v = \text{Some } m' \),

- Disjoint case: load \( m' \tau' b' i' = \text{load } m \tau' b' i' \) if \( b' \neq b \) or \( i' + |\tau'| \leq i \) or \( i + |\tau| \leq i' \)
- Compatible case: load \( m' \tau' b i = \text{Some(conver } \tau' v) \) if \( |\tau'| = |\tau| \)
- Incompatible case: if load \( m' \tau' b i = \text{Some } v' \) and \( |\tau'| \neq |\tau| \), then \( v' = \text{undef} \)
- Overlapping case: if load \( m' \tau' b i' = \text{Some } v' \) and \( i' \neq i \) and \( i' + |\tau'| > i \) and \( i + |\tau| > i' \), then \( v = \text{undef} \)

Figure 2: The 4 cases of the load-after-store algebraic laws

RR n° 7987
The 4 cases of the “load after store” laws are depicted in figure 2. The disjoint case corresponds to a load outside the memory area affected by the store. In the compatible case, we load exactly from the memory area affected by the store, in which case we obtain the value just stored, after conversion to the destination type $\tau'$:

\[
\begin{align*}
\text{convert} (\text{Vint}(n)) \text{Mint8unsigned} &= \text{Vint}(8\text{-bit zero extension of } n) \\
\text{convert} (\text{Vint}(n)) \text{Mint8signed} &= \text{Vint}(8\text{-bit sign extension of } n) \\
\text{convert} (\text{Vint}(n)) \text{Mint16unsigned} &= \text{Vint}(16\text{-bit zero extension of } n) \\
\text{convert} (\text{Vint}(n)) \text{Mint16signed} &= \text{Vint}(16\text{-bit sign extension of } n) \\
\text{convert} (\text{Vint}(n)) \text{Mint32} &= \text{Vint}(n) \\
\text{convert} (\text{Vptr}(b,i)) \text{Mint32} &= \text{Vptr}(b,i) \\
\text{convert} (\text{Vfloat}(f)) \text{float32} &= \text{Vfloat}(f \text{ normalized to single precision}) \\
\text{convert} (\text{Vfloat}(f)) \text{float64} &= \text{Vfloat}(f) \\
\text{convert } v \tau &= \text{Vundef} \quad \text{in all other cases}
\end{align*}
\]

In the two remaining cases, “incompatible” and “overlapping”, the bytes being read by the load include some but not all of the bytes written by the store, possibly combined with other bytes that were not affected by the store. To specify the result of the load in these two cases, we would need to expose the byte-level representation of values in memory: are integers stored in big-endian or little-endian representation? What is the byte-level encoding of floats? etc. This is something we elected not to do in version 1 of the memory model. Therefore, we just say that the value read is Vundef, as if we were reading from an uninitialized memory area. This is one of the design decisions that we revisited in version 2 of the memory model.

3 Assessment of the memory model, version 1

3.1 Capability: Accounting for ISO C99 and popular C programming idioms

The CompCert memory model version 1 correctly models the memory behavior of C programs that conform to the ISO C99 standard [10]. As specified in section 6.5 of the C99 standard, a C “object” (memory-resident data) has an effective type, which is either its declared static type, if any, or the type of the latest assignment into this object, if it has no declared static type. A conformant program always accesses an object through an l-value whose type is compatible with that of the effective type of the object. Compatibility includes addition or removal of qualifiers, as well as changes in signedness. This corresponds to the “compatible” case of the load-after-store laws:

\[
\text{if } \text{store } m \tau b i v = \text{Some } m' \text{ and } |\tau'| = |\tau| \text{ then load } m' \tau' b i = \text{Some}(\text{convert}(\tau', v))
\]

Indeed, two C types $t, t'$ that are compatible in the sense of the C99 standard encode into CompCert memory chunks $\tau, \tau'$ that have the same size (and differ only in signedness). Moreover, the C semantics guarantee that the value $v$ being stored with type $t$ has been normalized (casted) to type $t$ before storing. In this case, CompCert’s conversion-at-load-time $\text{convert}(\tau', v)$ behaves like the C type cast ($t'$) $v$.

Besides standard-conformant C programs, the CompCert memory model can give meaning to several popular C programming idioms that have undefined behavior according to the C standards. For example, in CompCert, the representation of pointer values is independent of...
their static pointer types. Therefore, casting from any pointer type to any other pointer type and then back to the original pointer type is well defined and behaves like the identity function:

```c
int x = 3;
*((int *) (double *) &x) = 4;  // equivalent to "x = 4;"
```

For another example, CompCert memory blocks are accessed at byte offsets within a block. The CompCert C and C Light semantics compute the byte offsets corresponding to array elements or struct fields before performing memory accesses [4]. This makes it possible to give semantics to non-conformant programs that access elements of arrays or structs via nonstandard casts or pointer arithmetic. For example:

```c
struct { int x, y, z; } s;
s.y = 42;
((int *) &s)[1] = 42;
*((int *) ((char *) &s + sizeof(int))) = 42;
```

All three assignments above are well defined in CompCert C and have the same semantics, namely storing the integer 42 at offset 4 in the block associated with variable `s`.

The same tolerance applies to non-discriminated unions. Consider:

```c
union point3d {
    struct { double x, y, z; } s;
    double d[3];
};
```

### 3.2 Limitation: No access to in-memory data representations

Systems or library C codes often cannot be written in standard-conformant C because they need to operate over the in-memory representation of data, at the level of individual bytes or bits. For example, changing the endianness of an integer (converting it from little-endian to big-endian representation, or conversely) is often written as follows:

```c
unsigned int bswap(unsigned int x)
{
    union { unsigned int i; char c[4]; } src, dst;
    int n;
    src.i = x;
    dst.c[3] = src.c[0]; dst.c[2] = src.c[1];
    dst.c[1] = src.c[2]; dst.c[0] = src.c[3];
    return dst.i;
}
```

In this example, the memory objects for `src` and `dst` are accessed simultaneously with types `int` and `char`. This is not supported by version 1 of the CompCert memory model: we fall in the “incompatible” and “overlapping” cases of the load-after-store laws, therefore `src.c[0]`, ..., `src.c[3]` read as `Vundef` values, and likewise `dst.i` reads as `Vundef` instead of the byte-reversed value of `x` as expected.

The example above is not too serious because it can be rewritten into standard-conformant code:
unsigned int bswap(unsigned int x)
{
    return (x & 0xFF) << 24 | (x & 0xFF00) << 8
        | (x & 0xFF0000) >> 8 | (x & 0xFF000000) >> 24;
}

More delicate examples arise in floating-point libraries that need to exploit the IEEE 754 bit-level representation of floating-point numbers to implement basic float operations. For instance, taking the absolute value of a single-precision IEEE 754 float amounts to clearing the top bit of its representation:

float fabs_single(float x)
{
    union { float f; unsigned int i; } u;
    u.f = x;
    u.i = u.i & 0x7FFFFFFF;
    return u.f;
}

Giving semantics to this function using the CompCert memory model version 1, we obtain that it always returns Vundef instead of the expected float result: the read u.i after the write u.f falls in the “incompatible” case of the load-after-store laws.

Sometimes, “bit surgery” over floating-point numbers must be performed by the compiler itself, to implement primitive C operations for which the microprocessor provides no dedicated instructions. For example, the PowerPC 32 bits architecture lacks an instruction to convert a 32-bit integer to a double-precision float. This conversion must be implemented by machine code equivalent to the following C code:

double double_of_signed_int(int x)
{
    union { double d; unsigned int i[2]; } a, b;
    a.i[0] = 0x43300000; a.i[1] = 0x80000000;
    b.i[0] = 0x43300000; b.i[1] = 0x80000000 + x;
    return b.d - a.d;
}

This code exploits not only the fact that the PowerPC is a big-endian architecture, but also the bit-level IEEE 754 representation: the bit pattern of a, namely, 0x4330000080000000 represents the float $2^{52} + 2^{31}$, and the bit pattern of b represents the float $2^{52} + 2^{31} + (\text{double})x$; moreover, the floating-point subtraction between these two floats is exact, resulting in (double)x. Again, version 1 of the CompCert memory model fails to give the intended semantics to this code, predicting an Vundef result instead.

Finally, some library functions work over byte-level data representations in a highly-portable (but not standard-conformant) manner. This is the case for the following naive implementation of the memcpy function from the C standard library:

void * memcpy(void * dest, const void * src, size_t n)
{
    for (i = 0; i < n; i++)
        ((char *) dest)[i] = ((const char *) src)[i];
    return dest;
}
According to the CompCert memory model version 1, this `memcpy` works as intended if it is passed arrays of `char` (signed or unsigned), or other compound types consisting only of `char` fields. Otherwise, for example if `src` points to an array of `int` or `double`, the read `((const char *) src)[i]` returns `Vundef`, and the destination block `dest` is filled with `Vundef` values.

### 3.3 Capability: Invariance by memory transformations

In the implementation of the memory model, block identifiers are integers and are assigned consecutively at each `alloc` operation. However, the operations of the memory model and the CompCert C formal semantics are insensitive to this particular choice of block identifiers. For instance, the CompCert C semantics, following the C99 standard, enables programs to test whether two block identifiers are equal (using the `==` pointer comparison), but not whether one identifier was allocated before another one (the `<` comparison is undefined between pointers designating different blocks). Consider two programs that are identical except for the order of definition of some variables:

```c
int x = 10;
int y = 20;
/* some code */
```

When executed according to the CompCert C semantics, the program on the left will bind `x` to (say) block identifier 1 and `y` to block 2, while the program on the right will bind `x` to block 2 and `y` to block 1. Nonetheless, the observable behaviors of the two programs are the same, because both the memory model and the CompCert C semantics are invariant by a renaming of block identifiers.

Invariance properties stronger than renamings are necessary to prove the correctness of CompCert’s compiler passes. Here are two examples of compilation passes that modify the memory layout of the program in nontrivial ways:

1. In an early simplification pass, producing Cminor intermediate code, local scalar variables whose addresses are never taken (using the `&` operator) are “pulled out of memory” and made to reside in a variable environment separate from the memory state. (This enables much more aggressive optimizations on uses of these variables.) Moreover, to simplify the semantics of Cminor and later intermediate languages, the remaining local variables are packed together as sub-blocks of a single memory block representing the stack frame of the function.

2. In the “stacking” pass performed after register allocation, local variables that could not be allocated to register are “spilled” to memory locations within the stack frame of the current function. This stack frame, therefore, needs to be extended to make room for spilled variables.

The effect of these two program transformations on the memory states are depicted in figure 3.

To reason about such transformations, CompCert introduces the notion of memory injections, which are a generalization of renamings of block identifiers. A memory injection is a function `F` with type

```
F : block → option(block × Z)
```

Let `b` be a block identifier in the memory state of the original program. `F(b) = None` means that this block was “pulled out of memory” by the program transformation. `F(b) = Some(b', δ)` means that this block is mapped to a sub-block of block `b'` in the memory state of the transformed program, said sub-block starting at offset `δ`. 
A memory injection $F$ induces a relation $F \vdash v_1 \leftrightarrow v_2$ between the values $v_1$ of the original program and the values $v_2$ of the transformed program. This relation corresponds to relocating pointer values as specified by $F$. It also enables $V_{undef}$ values in the original program to be replaced by more defined values in the transformed program.

$$F \vdash V_{undef} \leftrightarrow v_2 \quad F \vdash V_{int}(n) \leftrightarrow V_{int}(n) \quad F \vdash V_{float}(n) \leftrightarrow V_{float}(n)$$

$$F(b_1) = \text{Some}(b_2, \delta) \quad i_2 = i_1 + \delta$$

$$F \vdash V_{ptr}(b_1, i_1) \leftrightarrow V_{ptr}(b_2, i_2)$$

Likewise, a memory injection $F$ induces a relation $F \vdash m_1 \mapsto m_2$ between the memory states $m_1$ of the original program and $m_2$ of the transformed program. In version 1 of the CompCert memory model, this relation is defined as “every load in $m_1$ from a mapped block is simulated by a load in $m_2$ from the image of this block”:

$$F(b_1) = \text{Some}(b_2, \delta) \land \text{load } \tau \ m_1 \ b_1 \ i = \text{Some}(v_1) \quad \Rightarrow \exists v_2, \text{load } \tau \ m_2 \ b_2 \ (i + \delta) = \text{Some}(v_2) \land F \vdash v_1 \leftrightarrow v_2$$

As demonstrated by Leroy and Blazy [12, section 5], memory injections enjoy nice properties of commutation with the store, alloc and free operations of the memory model. These properties, in turn, support the proof of semantic preservation for the CompCert compiler passes that modify the memory behaviors of programs.

In conclusion, a crucial feature of the CompCert memory model version 1 is that block identifiers are kept relatively abstract and can be renamed, deleted or injected as sub-blocks of bigger blocks while preserving the observable behaviors of programs. Without this feature, several passes of the CompCert compiler could not be proved to preserve semantics.

### 3.4 Limitation: Coarse-grained access control

In version 1 of the memory model, a load or store operation succeeds as long as the accessed location is aligned and within the bounds of its enclosing block, and a free operation always succeeds, even if the given block was already freed. This behavior is too coarse in several situations that we now illustrate.

First, it should be the case that free fails if the given block has not been allocated before, or was already freed earlier. In this way, programs that perform double-free errors have undefined semantics, like they should. Attempts to free global variables should also fail, for similar reasons.
Second, memory blocks corresponding to const variables in C or to string literals should be marked read-only, so that a store into one of these blocks always fails. Besides making the semantics of CompCert C closer to the C standards, reflecting const-ness into the memory model in this way supports interesting optimizations such as constant propagation of const global variables:

\[
\text{const int } \text{cst} = 4; \quad \rightarrow \quad \text{const int } \text{cst} = 4;
\]

\[
\text{int } f(x) \{ \text{return } x \ast \text{cst}; \} \quad \rightarrow \quad \text{int } f(x) \{ \text{return } x \ll 2; \}
\]

Third, fine-grained access control over memory locations is also useful to extend CompCert towards data race-free concurrent programs, as proposed by Appel et al. in the Verified Software Toolchain project [2, 3, 9].

In their approach, data races are avoided by a locking discipline enforced via a concurrent separation logic [14, 9]. Each area of shared memory is logically associated with a lock through concurrent separation logic formulas. When a thread releases an exclusive lock, the calling thread loses all access rights on the associated memory area. If, later, this lock is reacquired, the calling thread recovers these rights. Since their concurrent separation logic supports fractional permissions, it is also possible for a thread to temporarily abandon write rights, giving other threads the right to read (but not write) to this memory area, while retaining read rights for itself.

At the source language level, the access rights mentioned above are implied and enforced by the separation logic. The CompCert compiler must, then, guarantee that these access rights are respected during compilation. A typical violation would be for CompCert to move a load or store before a lock acquisition or after a lock release. One way to prove that this does not happen would be to apply the separation logic discipline to all intermediate languages and compilation passes of CompCert. A much simpler approach, which we follow in version 2 of the CompCert memory model, is to equip the memory model with a notion of fine-grained, per-byte permissions, governing for instance whether a byte can be written to. Concurrent operations such as lock and unlock are, then, modeled as changing the memory permissions as well as memory contents in an unpredictable manner, under control of an oracle external to the semantics. This suffices to prevent the compiler from moving memory accesses across lock and unlock operations.

The changes to memory permissions that occur at external function calls—in what appears to CompCert to be an “unpredictable” manner—can be reasoned about in a logic \textit{external} to CompCert and its memory model. That logic might use fractional or token-based permission models [8] to prove race freedom in a very predictable way. These complex permission models do not need to be completely reified into the CompCert memory model; instead, a summary of their effects can be described by the abstract permissions that we will show in section 4.2.

4 The CompCert memory model, version 2

We now describe version 2 of the CompCert memory model, which enhances version 1 to address the limitations described in sections 3.2 and 3.4, to the extent that the good properties described in sections 3.1 and 3.3 still hold. The main changes, described in more detail in the following sections, are:

- Exposing the byte-level, in-memory representation of integers and floats, while keeping that of pointers abstract (section 4.3).
- Introducing fine-grained, byte-level permissions in replacement for memory bounds (section 4.2).
Adding new operations over memory states: loadbytes, storebytes, and drop_perm (section 4.1).

4.1 Operations

In the new memory model, memory states are presented as a type mem, a constant empty : mem denoting the empty memory state, and the 7 operations:

- \( \text{alloc} : \text{mem} \to Z \times \text{block} \)
- \( \text{free} : \text{mem} \to \text{block} \to Z \to Z \to \text{option mem} \)
- \( \text{load} : \text{mem} \to \text{memory\_chunk} \to \text{block} \to Z \to \text{option mem} \)
- \( \text{store} : \text{mem} \to \text{memory\_chunk} \to \text{block} \to Z \to \text{val} \to \text{option mem} \)
- \( \text{loadbytes} : \text{mem} \to \text{block} \to Z \to Z \to \text{option (list memval)} \)
- \( \text{storebytes} : \text{mem} \to \text{block} \to Z \to \text{list memval} \to \text{option mem} \)
- \( \text{drop\_perm} : \text{mem} \to \text{block} \to Z \to Z \to \text{permission} \to \text{option mem} \)

\( \text{alloc}, \text{load} \) and \( \text{store} \) are as in version 1 of the model. The \( \text{free} \) operation, \( \text{free} m b l h \), no longer frees the whole block \( b \), but rather the range of offsets \([l, h)\) within block \( b \). This change simplifies the definition of a separation logic on top of the memory model. It also makes it possible to reduce the size of a block after allocation, and to "punch holes" within a block, two possibilities that CompCert does not exercise currently. Another change is that \( \text{free} \) can now fail, typically if the locations to be freed have been freed already.

Three new operations were added. loadbytes and storebytes are similar to \( \text{load} \) and \( \text{store} \), but instead of reading or writing a value, they read or write a list of byte contents (type \( \text{memval} \), explained in section 4.3 below). loadbytes and storebytes are useful to give semantics to block copy operations such as memcpy, and also to reason over byte-level, in-memory representation of data.

Finally, \( \text{drop\_perm} m b l h p \) lowers the permissions (access rights) over locations \( (b, l), \ldots, (b, h - 1) \), setting them to \( p \). Permissions are further explained in section 4.2 below. A typical use of \( \text{drop\_perm} \) is to set to read-only a memory block corresponding to a const C variable, after it has been initialized.

4.2 Permissions

Memory states associate permissions, or access rights, to every byte location. The various permissions are:

- Freeable:
  full permissions: can compare, read, write, and free
- Writable:
  can compare, read and write but not free
- Readable:
  can compare and read but not write nor free
- Nonempty:
  can only compare

In the table above, "compare" refers to the ability of comparing a pointer to the given location with other pointers.\(^1\)

Permissions are cumulative: having permission \( p \) implies having all permissions \( p' < p \), where the ordering on permissions is

\[ \text{Nonempty} < \text{Readable} < \text{Writable} < \text{Freeable} \]

\(^1\text{In CompCert C as in the C standards, pointer comparison involving invalid pointers (e.g. pointers to freed locations) have undefined semantics. For the purpose of giving semantics to pointer comparisons, we take that a pointer \( \text{Ptr}(b, i) \) is valid if the location \((b, i)\) has at least \text{Nonempty} permission.} \]
The CompCert memory model version 2

unlock
write lock

Figure 4: An example of evolutions of Max and Cur permissions for a location

It is possible for a location to have no permission at all. In this case, we say that the location is empty. This is typically the case for locations that have not been allocated yet, or have been freed already.

Every byte location is associated not to one, but to two permissions: the current permission and the maximal permission. At any time in the execution, the current permission is less than or equal to the maximal permission. The maximal permission evolves predictably throughout the lifetime of the location: when the location is allocated, it has maximal permission Freeable; this permission can later be lowered by a drop_perm operation; finally, freeing the location removes all its maximal permissions, making the location empty. Note that the maximal permission can only decrease once the location has been allocated. In contrast, the current permission can decrease or increase (without ever exceeding the maximal permission) during the lifetime of the location.

For example, in the extension to shared memory concurrency outlined in section 3.4, an unlock operation temporarily drops current permissions, which can be recovered by a subsequent lock operation. Figure 4 illustrates this evolution of permissions throughout the lifetime of a location.

In the Coq formalization, the association of permissions to locations is exposed as a predicate:

\[
\text{perm} : \text{mem} \rightarrow \text{block} \rightarrow \mathbb{Z} \rightarrow \text{perm\_kind} \rightarrow \text{permission} \rightarrow \text{Prop}
\]

where perm_kind is the enumerated inductive type \( \text{Max} \mid \text{Perm} \). The proposition \( \text{perm} m b i k p \) holds if and only if in memory state \( m \), location \((b, i)\) has \( k\)-permission at least \( p \). The cumulativity of permissions, and the fact that current permissions are never above maximal permissions, are expressed by the following implications:

\[
\begin{align*}
\text{perm} m b i k p \land p' \leq p & \Rightarrow \text{perm} m b i k p' \\
\text{perm} m b i \text{Cur} p & \Rightarrow \text{perm} m b i \text{Max} p
\end{align*}
\]

Instead of checking block offsets against block bounds, as in version 1 of the memory model, the load and store operations check that the accessed locations have current permissions at least Readable, resp. Writable. Likewise, the free and drop_perm operations check that the affected locations have current permissions at least Freeable. Defining

\[
\text{Definition range\_perm} (m: \text{mem}) (b: \text{block}) (lo hi: \mathbb{Z}) (k: \text{perm\_kind}) (p: \text{permission}) : \text{Prop} := \\
\forall \text{ofs}, lo \leq \text{ofs} < hi \rightarrow \text{perm} m b \text{ofs} k p.
\]

we have the following properties:
Owing to the availability of per-byte permissions, it is no longer useful to associate low and high bounds to memory blocks. Version 2 of the memory model therefore removes the low_bound and high_bound functions of version 1. The main use of these functions in CompCert’s proofs was to state that a location \((b, i)\) is valid, i.e. already allocated but not yet freed, using the following definition:

\[(b, i)\] is valid in \(m \triangleq \text{low\_bound } m \leq b \leq \text{high\_bound } m b\]

Using version 2 of the model, the following alternate definition works just as well:

\[(b, i)\] is valid in \(m \triangleq \text{perm } m b i \text{ Max Nonempty}\]

Permissions are preserved by operations over memory states, with the following exceptions.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Effect on permissions</th>
</tr>
</thead>
<tbody>
<tr>
<td>alloc (m l h = (m', b))</td>
<td>locations ((b, i)\ldots(b, h - 1)) get Freeable permissions (Max and Cur)</td>
</tr>
<tr>
<td>free (m b l h)</td>
<td>locations ((b, i)\ldots(b, h - 1)) lose all permissions</td>
</tr>
<tr>
<td>drop_perm (m b l h p)</td>
<td>locations ((b, i)\ldots(b, h - 1)) get Max and Cur permissions (p)</td>
</tr>
</tbody>
</table>

To strengthen intuitions about permissions, it is useful to consider their meaning in an hypothetical shared-memory concurrent extension of CompCert. In such an extension, different threads have different permissions over a given memory location. Using a concurrent separation logic with fractional permissions [8], and projecting these rich logical permissions on CompCert’s simple permissions, we can ensure that the permissions of two threads \(A\) and \(B\) over a given memory location always fall within one of the following cases:

<table>
<thead>
<tr>
<th>(A)’s permission</th>
<th>(B)’s permission</th>
<th>What (A) can do</th>
<th>What (B) can do</th>
</tr>
</thead>
<tbody>
<tr>
<td>Freeable</td>
<td>none</td>
<td>compare, load, store, free</td>
<td>nothing</td>
</tr>
<tr>
<td>Writeable (\leq) Nonempty</td>
<td>compare, load, store</td>
<td>compare</td>
<td></td>
</tr>
<tr>
<td>Readable (\leq) Readable</td>
<td>compare, load</td>
<td>compare, load</td>
<td></td>
</tr>
<tr>
<td>Nonempty (\leq) Writable</td>
<td>compare</td>
<td>compare, load, store</td>
<td></td>
</tr>
<tr>
<td>none</td>
<td>any</td>
<td>nothing</td>
<td>compare, load, store, free</td>
</tr>
</tbody>
</table>

Combined with the permission checks performed by the various operations, this interpretation of permissions causes programs containing data races to have undefined semantics (“getting stuck”). If two threads are in danger of approaching a data race, at least one of the threads will be “stuck” in its own sequential operational semantics because it will have insufficient permission. For example, if thread \(A\) stores at a location while thread \(B\) loads from the same location, one or both of the load and store operations will fail by lack of sufficient permissions. A similar failure occurs if \(A\) compares a pointer while \(B\) is freeing the location. However, concurrent loads are possible if the location has permission Readable in both threads.

### 4.3 In-memory data representations

Memory states include a contents map that associates a value of type \(memval\) to each byte, that is, each pair (block identifier, byte offset).
Inductive memval: Type :=
| Undef : memval
| Byte : byte -> memval
| Pointer : block -> int -> nat -> memval.

The contents of a given memory byte can be either

- **Undef**, standing for an unspecified bit pattern such as the contents of an uninitialized memory area;
- **Byte n**, where \( n \) is a concrete 8-bit integer in the range \( 0 \ldots 255 \);
- **Pointer \( b \ i \ n \)**, standing for the \( n \)-th byte of the abstract pointer \( (b, i) \).

The intent of this representation is that integer and float values, when stored in memory, are decomposed into a sequence of bytes \( n_1, \ldots, n_k \), taking endianness and IEEE encoding of floats into account, then stored in the contents map as the memvals Byte \( n_1, \ldots, \text{Byte } n_k \). (This is exactly what the hardware processor does.) In contrast, when storing a pointer value \( \text{Vptr}(b, i) \), we hide its hardware representation by storing the memvals Pointer \( b \ i \ 0, \ldots, \text{Pointer } b \ i \ 3 \). Loading from memory performs the reverse operation, recovering a value from a sequence of memvals.

These conversions between values and lists of memvals are governed by a memory quantity ("chunk") and encapsulated in the following two functions:

\[
\begin{align*}
\text{encode_val : memory_chunk} & \rightarrow \text{val} \rightarrow \text{list memval} \\
\text{decode_val : memory_chunk} & \rightarrow \text{list memval} \rightarrow \text{val}
\end{align*}
\]

Here is the shape of the definition of \text{encode_val}:

\[
\begin{align*}
\text{encode_val Mint16signed } (\text{Vint}(n)) = & \text{[Byte } x_1\text{]} \text{ where } (x_1) = \text{encode_int } 1 \ n \\
\text{encode_val Mint8signed } (\text{Vint}(n)) = & \text{[Byte } x_1\text{]} \text{ where } (x_1) = \text{encode_int } 1 \ n \\
\text{encode_val Mint16unsigned } (\text{Vint}(n)) = & \text{[Byte } x_1; \text{Byte } x_2\text{]} \text{ where } (x_1, x_2) = \text{encode_int } 2 \ n \\
\text{encode_val Mint32 } (\text{Vint}(n)) = & \text{[Byte } x_1; \text{Byte } x_2; \text{Byte } x_3; \text{Byte } x_4\text{]} \\
& \text{ where } (x_1, \ldots, x_4) = \text{encode_int } 4 \ n \\
\text{encode_val\ Vptr } (b, i) = & \text{[Pointer } b \ i \ 0; \text{Pointer } b \ i \ 1; \text{Pointer } b \ i \ 2; \text{ Pointer } b \ i \ 3\text{]} \\
\text{encode_val Mfloat32 } (\text{Vfloat}(n)) = & \text{[Byte } x_1; \text{Byte } x_2; \text{Byte } x_3; \text{Byte } x_4\text{]} \\
& \text{ where } (x_1, \ldots, x_4) = \text{encode_int } 4 \text{ (bits_of_single } n\text{)} \\
\text{encode_val Mfloat64 } (\text{Vfloat}(n)) = & \text{[Byte } x_1; \ldots; \text{Byte } x_8\text{]} \\
& \text{ where } (x_1, \ldots, x_8) = \text{encode_int } 8 \text{ (bits_of_double } n\text{)} \\
\text{encode_val } \tau \ v = & \text{[Undef}; \ldots; \text{Undef} \text{]} \text{ (|}\tau\text{| times Undef)} \text{ otherwise}
\end{align*}
\]

Here, \text{encode_int } l \ n \ returns the list of the low \( l \) bytes of integer \( n \), either in big-endian or little-endian order depending on the target architecture. \text{bits_of_single} and \text{bits_of_double} return as an integer the IEEE 754 representation of a single-precision or double-precision float, respectively.

The \text{decode_val} function is also defined by case analysis, in a manner symmetrical to that of \text{encode_val}.
decode_val Mint8unsigned [Byte x1] = Vint(n)

where n = decode_int [x1]

decode_val Mint8signed [Byte x1] = Vint(sign_extends(n))

where n = decode_int [x1]

decode_val Mint16unsigned [Byte x1; Byte x2] = Vint(n)

where n = decode_int [x1; x2]

decode_val Mint16signed [Byte x1; Byte x2] = Vint(sign_extends(n))

where n = decode_int [x1; x2]

decode_val Mint32 [Byte x1;...;Byte x4] = Vint(n)

where n = decode_int [x1;...;x4]

decode_val Mfloat32 [Byte x1;...;Byte x4] = Vfloat(single_of_bits(n))

where n = decode_int [x1;...;x4]

decode_val Mfloat64 [Byte x1;...;Byte x8] = Vfloat(double_of_bits(n))

where n = decode_int [x1;...;x8]

decode_val τ L = Vundef in all other cases

Here, decode_int L combines the given list of bytes L into an integer, using either big-endian or little-endian convention depending on the target architecture.

The decode_val function is carefully engineered to be the left inverse of encode_val: encoding a value, then decoding the resulting list of bytes, recovers the original value modulo normalization of the value to the memory type used:

decode_val τ (encode_val τ v) = convert τ v

This property still holds if the bytes are decoded with an integer memory type τ' that differs only in signedness from the memory type τ used for encoding:

decode_val τ’ (encode_val τ v) = convert τ’ v

if {τ, τ'} = {Mint8unsigned, Mint8signed}

or {τ, τ'} = {Mint16unsigned, Mint16signed}

Moreover, encoding as a Mint32 and decoding as a Mfloat32, or conversely, gives access to the IEEE bit-level representation of single-precision floats:

decode_val Mfloat32 (encode_val Mint32 (Vint(i))) = single_of_bits(i)

decode_val Mint32 (encode_val Mfloat32 (Vfloat(f))) = bits_of_single(f)

4.4 Algebraic laws

Load and loadbytes; store and storebytes  A load operation is equivalent to a loadbytes operation plus a decode_val and an alignment check:

load m τ b i = Some (decode_val τ B) ⇔ loadbytes m b i |τ| = Some B ∧ (τ) divides i

Similarly for a store operation and the corresponding storebytes operation:

store m τ b i v = Some m' ⇔ storebytes m b i (encode_val τ v) = Some m' ∧ (τ) divides i
The CompCert memory model version 2
Decomposing loadbytes and storebytes operations A loadbytes operation on a range of locations is equivalent to two loadbytes operations on two adjacent ranges:

\[
\text{loadbytes } m \ b \ i \ (n_1 + n_2) = \text{Some } B \iff \exists B_1, B_2, \text{ loadbytes } m \ b \ i \ n_1 = \text{Some } B_1 \\
\land \text{ loadbytes } m \ b \ (i + n_1) \ n_2 = \text{Some } B_2 \\
\land B = B_1, B_2
\]

Likewise, a storebyte operation decomposes into two storebytes:

\[
\text{storebytes } m \ b \ i (B_1, B_2) = \text{Some } m' \iff \exists m_1, \text{ storebytes } m \ b \ i \ B_1 = \text{Some } m_1 \\
\land \text{ storebytes } m_1 \ b \ (i + |B_1|) \ B_2 = \text{Some } m'
\]

Load after alloc Same properties as in version 1 of the model: if alloc \( m \ l \ h = (m', b) \),
- if load \( m \ \tau \ b \ i \ n = \text{Some } v \), then \( v = \text{Vundef} \)

Load after free: if free \( m \ b \ l \ h = m' \),
- load \( m' \ \tau' \ b' \ i' = \text{load } m \ \tau' \ b' \ i' \text{ if } b' \neq b \)
- If load \( m \ \tau \ b \ i \ = \text{Some } v \), then \( v = \text{Vundef} \)

Loadbytes after storebytes If storebytes \( m \ b \ i \ B = \text{Some } m' \),
- Compatible case: loadbytes \( m' \ b \ i \ |B| = \text{Some } B \)
- Disjoint case: loadbytes \( m' \ b' \ i' \ n' = \text{loadbytes } m \ b' \ i' \ n' \text{ if } b' \neq b \text{ or } i' + n' \leq i \text{ or } i + |B| \leq i' \)

Cases of partial overlap can be reasoned upon by decomposing the storebytes or the loadbytes operation into multiple operations.

Load after store if store \( m \ \tau \ b \ i \ v = \text{Some } m' \),
- Disjoint case: load \( m' \ \tau' \ b' \ i' = \text{load } m \ \tau' \ b' \ i' \text{ if } b' \neq b \text{ or } i' + |\tau'| \leq i \text{ or } i + |\tau| \leq i' \)
- Compatible case: load \( m' \ \tau' \ b \ i = \text{decode_val } \tau' (\text{encode_val } \tau \ v) \text{ if } |\tau'| = |\tau| \).

In particular, if \( \tau' \) and \( \tau \) are identical or differ only in signedness, load \( m' \ \tau' \ b \ i = \text{convert } \tau' \ v \).

Compared with version 1 of the memory model, it is no longer the case that the load must return a Vundef value in the “incompatible” and “overlapping” cases. For example, if we write a 64-bit float \( f \) at location \((b, i)\), then read a 32-bit integer from this location, the result is not Vundef but an integer corresponding to one half of the IEEE bit-level representation of \( f \). This is a strength of the new memory model, as it addresses the limitations described in section 3.2. However, we can still say something in the “incompatible” and “overlapping” cases if the value \( v \) just stored is a pointer value.

- Incompatible case for pointer values: if \( v \) is a pointer value and load \( m' \ \tau' \ b \ i = \text{Some } v' \) and \( \tau \neq \text{Mint32} \lor \tau' \neq \text{Mint32} \), then \( v' = \text{Vundef} \).
- Overlapping case for pointer values: if \( v \) is a pointer value and load \( m' \ \tau' \ b \ i' = \text{Some } v' \) and \( i' \neq i \text{ and } i' + |\tau'| > i \text{ and } i + |\tau| > i' \), then \( v' = \text{Vundef} \).

These special cases are related to a more general integrity property for stored pointer values, described next.

RR n° 7987
Integrity of pointer values  As discussed above, it is possible to load integer or float values that were never stored in memory, but arise from combinations of byte-level representations of other integer or float values previously stored in memory. However, the memory model guarantees that this cannot happen for pointer values:

If store $m \tau b i v = \text{Some} \ m'$ and load $m' \tau' b' i' = \text{Some}(\text{Vptr}(b'',i''))$, then either

- the pointer value that is loaded is the value just stored: $\tau = \tau' = \text{Mint32}$ and $b' = b$ and $i' = i$ and $v = \text{Vptr}(b'',i'')$;
- or the load is disjoint from the store: $b' \neq b$ or $i' + |\tau| \leq i$ or $i + |\tau| \leq i'$; therefore, the pointer value that is loaded was already present in the original memory state: load $m \tau' b' i' = \text{Some}(\text{Vptr}(b'',i''))$

This integrity property is important: if pointer values could arise “out of thin air” by loading byte-level representations of other values, the properties of invariance by memory transformations (section 3.3) would be invalidated, and several passes of the CompCert compiler could no longer be proved semantics-preserving.

4.5 Implementation

The CompCert Coq sources provide an implementation of the memory model in module Mem, which is proved to satisfy the algebraic laws listed above and all the other properties specified in module MemType. We briefly outline this implementation, referring the reader to the commented Coq development for more details. Memory states are represented by the following record type:

```
Definition block : Type := Z.

Record mem : Type := mkmem {
  mem_contents: ZMap.t (ZMap.t memval);
  mem_access: ZMap.t (Z -> perm_kind -> option permission);
  nextblock: block;
  nextblock_pos: nextblock > 0;
  access_max:
    forall b ofs, perm_order'' (mem_access#b ofs Max) (mem_access#b ofs Cur);
  nextblock_noaccess:
    forall b ofs k, b <= 0 \b => nextblock -> mem_access#b ofs k = None

A memory state is composed of three pieces of data:

- A block identifier nextblock, which tracks the first non-allocated block. This is the block identifier that the next alloc operation will return as result.
- A map mem_contents from (block, offset) pairs to memvals. This map is implemented using the ZMap data structure from CompCert’s Maps library. ZMap provides an efficient implementation of $\mathbb{Z}$-indexed finite maps with a default value.
- A map mem_access from (block, offset, permission-kind) triples to the type option permission. This maps records, for every location, the greatest Cur permission and the greatest Max permission. None means no permissions at all.

Additionally, three invariants are packaged with this data:

- The next block is always positive. (Negative block identifiers are reserved by CompCert to represent function pointers.)
• For every location, the Cur permission never exceeds the Max permission.
• Blocks that have not been allocated yet have empty permissions.

To give a flavor of the implementation, here is the definition of the store operation:

\[
\text{Definition store } (\text{chunk: memory_chunk}) (\text{m: mem})
\]
\[
(b: \text{block}) (\text{ofs: } \mathbb{Z}) (v: \text{val}) : \text{option mem} :=
\]
\[
\begin{align*}
\text{if } & \text{valid_access_dec m chunk b ofs Writable then} \\
& \text{Some (mkmem } (\text{ZMap.set b} \\
& \quad (\text{setN (encode_val chunk v) ofs } (\text{m.(mem_contents)#b})) \\
& \quad \text{m.(mem_access))} \\
& \quad \text{m.(nextblock)} \\
& \quad \text{m.(nextblock_pos)} \\
& \quad \text{m.(access_max)} \\
& \quad \text{m.(nextblock_noaccess))} \\
& \text{else} \\
& \text{None.}
\end{align*}
\]
valid_access_dec decides whether the offset is aligned with respect to the memory chunk and whether all addressed bytes have Cur,Writable permissions. If not, store fails, returning None. If so, an updated memory state is returned, where the locations \((b, \text{ofs}), \ldots, (b, \text{ofs}+|\text{chunk}|-1)\) are set (by the auxiliary function \(\text{setN}\)) to the list of \(\text{mem}v\)s returned by \(\text{encode\_val chunk v}\), and all other locations are unchanged.

Some clients of the CompCert memory model, such as libraries of lemmas about program transformations and program logics, often find it convenient to reason about the constructive definitions (such as the one shown here for store) instead of their axiomatizations. Other clients, such as the correctness proofs for CompCert’s compilation passes, only need the axiomatization in terms of algebraic laws outlined in section 4.4.

5 Assessment of the memory model, version 2

Version 2 of the memory model preserves the main features of version 1, discussed in section 3, namely:

• It gives the expected semantics to C programs that conform to ISO C99.
• It gives the expected semantics to those nonconformant C programs that perform wild casts between pointers and make assumptions about the memory layout of composite types (structs, unions, and arrays).
• It enjoys useful properties of invariance by memory transformations. The notion of memory injections initially developed for version 1 extends easily to version 2 of the model and was shown to commute with memory operations. The proofs of semantic preservation for CompCert’s compilation passes were relatively easy to adapt to version 2 of the memory model.

We now discuss the improvements brought by version 2 on the limitations of version 1.

5.1 Capability: Accounting for low-level programming idioms on integers and floats

Version 2 of the memory model is able to give precise semantics to programs that make assumptions about the memory representations of base types (integers and floats). We now revisit the
examples of section 3.2 to illustrate this new capability.

**Endianness change**

```c
unsigned int bswap(unsigned int x) {
    union { unsigned int i; char c[4]; } src, dst;
    int n;
    src.i = x;
    /* point 1 */
    dst.c[3] = src.c[0]; dst.c[2] = src.c[1];
    dst.c[1] = src.c[2]; dst.c[0] = src.c[3];
    /* point 2 */
    return dst.i;
}
```

Using the store-storebytes equivalence, we see that at program point 1, the memory block associated with src contains the encoding \([\text{Byte } x_1; \text{Byte } x_2; \text{Byte } x_3; \text{Byte } x_4]\) of the integer \(x\), where \((x_1, \ldots, x_4) = \text{encode}_\text{int} 4 \times x\).

Using the loadbytes-storebytes laws, we obtain that at program point 2, the memory block associated with dst contains the memvals \([\text{Byte } x_4; \text{Byte } x_3; \text{Byte } x_2; \text{Byte } x_1]\).

The load-loadbytes equivalence, then, shows that the integer returned by the function is \(\text{decode}_\text{int} [x_4, x_3, x_2, x_1]\), which is indeed the byte-swapping of integer \(x\).

**Single-precision absolute value**

```c
float fabs_single(float x) {
    union { float f; unsigned int i; } u;
    u.f = x;
    /* point 1 */
    u.i = u.i & 0x7FFFFFFF;
    /* point 2 */
    return u.f;
}
```

According to the load-store-compatible law, the value of \(u.i\) at program point 1 is

\[
\text{decode}_\text{val Mint32} (\text{encode}_\text{val Mfloat32} x) = \text{bits}_\text{of}_\text{single}(x)
\]

that is, the 32-bit integer corresponding to the IEEE 754 representation of the single-precision float \(x\).

Using the same law again, the return value of the function is \(\text{single}_\text{of}_\text{bits}(n)\), where \(n\) is the value of \(u.i\) at point 2. Since \(n = \text{bits}_\text{of}_\text{single}(x) \& 0x7FFFFFFF\), it follows that \(\text{fabs}_\text{single}\) computes the function

\[x \mapsto \text{single}_\text{of}_\text{bits}(\text{bits}_\text{of}_\text{single}(x) \& 0x7FFFFFFF)\]

Using a formalization of IEEE 754 such as FlocoQ [5], it can be proved that this function is floating-point absolute value.
Converting integers to double-precision floats, PowerPC-style

\[
\text{double double_of_signed_int(int x)}
\]
\[
\begin{align*}
\text{union } \{ \text{double } d; \text{unsigned int } i[2]; \} & \text{ a, b; } \\
\text{a.i[0]} & = 0x43300000; \quad \text{a.i[1]} = 0x80000000; \\
\text{b.i[0]} & = 0x43300000; \quad \text{b.i[1]} = 0x80000000 + x; \\
\text{/* point 1 */} \\
\text{return b.d - a.d; }
\end{align*}
\]

Using many of the memory model laws (store-storebytes and load-loadbytes equivalence; loadbytes-storebytes laws; and loadbytes and storebytes decomposition properties) and assuming a big-endian architecture, we obtain that at point 1,

\[
\begin{align*}
\text{a.d} & = \text{double_of_bits}(0x43300000080000000) \\
\text{b.d} & = \text{double_of_bits}(0x43300000080000000 + x)
\end{align*}
\]

The return value of the function is, therefore, the double-precision floating-point difference between these two floats. Using Flocq, it remains to prove that this difference is indeed the float (double) \(x\), taking advantage of the fact \(-2^{31} \leq x < 2^{31}\). The point is that the correctness of this function was reduced to a pure floating-point arithmetic problem; the byte-level manipulations over floats are now precisely defined thanks to the new memory model.

5.2 Limitation: No access to bit-level representations of pointers

Consider again the block copy example from section 3.2:

\[
\text{void * memcpy(void * dest, const void * src, size_t n)}
\]
\[
\begin{align*}
\text{for (i = 0; i < n; i++)} \\
\text{((char *) dest)[i]} & = ((const char *) src)[i]; \\
\text{return dest; }
\end{align*}
\]

Version 2 of the memory model is able to show that this function executes as expected, but only if the source array src contains no pointer values; more precisely, if the memvals at src... src+n−1 are all of the Byte or Uint kind.

Indeed, when loaded with C type char, the memval Byte \(x\) reads as the integer \(x\) or \(x\)'s sign extension (depending on whether the char type is signed). Storing this integer with C type char amounts to storing the memval Byte \(x\). If the source memval is Uint, it reads as the value Uint, and writes back as the memval Uint. Finally, if the source memval is a pointer fragment Pointer b i n, it reads as the value Uint and writes as Uint.

Assuming no overlap between the src and dest memory areas, the net effect of memcpy's loop is, therefore, to copy the memvals contained in src to the area pointed by dest, turning pointer fragments into Uint memvals and preserving Byte and Uint memvals. In other words, the expected behavior of memcpy, namely, making an exact copy of src into dest, is guaranteed by CompCert's semantics only if src contains integers and floats, but no pointers.

Similar limitations arise in examples other than memcpy. One is the memcmp function from the C standard library, which compares the contents of two memory areas as if they were arrays...
of characters. (Unlike `memcpy`, the informal semantics of `memcmp` is very unclear to begin with, in particular because it observes the values of padding bytes introduced by compilers in compound data structures.) Another example is the occasional need to reverse the endianness of a pointer, for instance when a big-endian processor exchanges linked data structures with a little-endian USB controller.

Is this a serious limitation? More practical experience with embedded critical codes is needed to answer this question, but here are a few thoughts about this issue.

First, the C standards guarantee the existence of a correct `memcpy` function in the C standard library, but never say that it can be written in conformant C, as the simple byte-per-byte copy loop above or in any other ways. Our memory model version 2 is perfectly able to axiomatize the behavior of such a correct `memcpy` function, as a `loadbytes` operation over the whole range `src...src+n-1` followed by a `storebytes` at `dest`.

Second, like many C compilers, CompCert provides a predefined block copy operation, `__builtin_memcpy`, whose semantics is precisely defined as a `loadbytes` operation followed by a `storebytes` (plus checks for absence of overlap). A current limitation of this built-in operation is that the number `n` of bytes to copy must be a compile-time constant. In exchange, CompCert is able to produce very efficient assembly code for `__builtin_memcpy`, using multi-byte memory accesses and unrolling the copy loop when appropriate. The point is that CompCert-compiled systems code should never define its own `memcpy` function and call it as `memcpy(dest, src, sizeof(src))`: using `__builtin_memcpy` is not only better defined semantically speaking, but also much more efficient.

Third, if the need arises to copy arrays of pointers, we can define a version of `memcpy` specialized for this case:

```c
void * memcpy_ptr(void ** dest, const void ** src, size_t n)
{
    for (i = 0; i < n / sizeof(void *); i++)
        dest[i] = src[i];
    return dest;
}
```

Both version 1 and version 2 of the CompCert memory model show that this function correctly copies arrays of pointers. With version 2, it might be possible to show that structs containing a mixture of pointer fields and numerical fields, or arrays of such structs, are copied unchanged as well. This conjecture relies on the fact that pointer fields in structs are always 4-aligned, and force the alignment of the enclosing struct to be at least 4.

5.3 Capability: fine-grained access control

The permission mechanism introduced in version 2 of the model is effective to better control the memory operations that are allowed on global variables, and also to support more aggressive optimizations in the CompCert compiler.

**More precise semantics** From the standpoint of the CompCert operational semantics, the initial memory state in which a program starts execution is built as follows. For every global variable of the C program, a memory block is allocated, then filled with the initial value provided for this variable, if any, or by a default value of “all zeroes” otherwise; then, permissions over the whole block are dropped to

- **Nonempty** if the type of the global variable carries the `volatile` modifier;
• Readable if this type carries the const modifier but not the volatile modifier;
• Writable, otherwise.

(CompCert treats string literals as global, initialized arrays of characters with type const char [], hence string literals, too, get Readable permissions.)

Dropping permissions over global variables has several benefits. First, attempting to deallocate a global variable or string literal by calling free on its address now has undefined semantics, as it should. (This follows from the fact that memory blocks corresponding to global variables always lack the Freeable permission.) Second, it is now a semantic error for a program to try to assign into a const global variable, or to access a volatile global variable through normal load and store operations.

The latter point deserves more explanations on how CompCert handles the volatile modifier. Accesses to l-values having volatile static type are compiled and given semantics not via normal load and store operations, but via special built-in functions, __builtin_volatile_read and __builtin_volatile_write that check whether the location actually accessed is an object declared volatile or not. In the former case, the volatile access is treated as an input/output operation, communicating with the outside world through an event in the trace of observables for the program, and bypassing the memory model entirely. In the latter case, the volatile access is treated as a regular load/store operation. To summarize:

<table>
<thead>
<tr>
<th>Static type</th>
<th>Semantics &amp; compilation</th>
<th>Actual location accessed</th>
</tr>
</thead>
<tbody>
<tr>
<td>not volatile</td>
<td>regular load/store operation</td>
<td>load/store error</td>
</tr>
<tr>
<td>volatile</td>
<td>__builtin_volatile operation</td>
<td>load/store I/O event</td>
</tr>
</tbody>
</table>

The semantic error in the top right case is a consequence of the accessed location lacking Readable and Writable permissions. It agrees with the prescriptions of the C standards, which state that undefined behavior arises if a volatile object is accessed through a non-volatile l-value, as can arise if a pointer cast is used to remove the volatile modifier from the type of the pointed object.

The discussion above is framed in terms of global variables. For function-local variables, CompCert essentially ignores the const and volatile modifiers: volatile local variables make little sense, as they cannot correspond to a hardware memory device; const local variables cannot have their permissions dropped, because there would be no way to raise these permissions back to Freeable before deallocating them at function return time.

**More aggressive optimizations** We improved the constant propagation pass of CompCert 1.11 to take advantage of the "const-ness" of global variables. Consider:

```c
const int n = 1;
const double tbl[3] = { 1.11, 2.22, 3.33 };
double f(void) { return tbl[n]; }
```

Owing to the const modifiers, the value of n is always 1 throughout execution, and the value of tbl[1] is always 2.22. It is therefore legitimate to optimize function f into

```c
double f(void) { return 2.22; }
```

This is what the improved constant propagation pass now does. Its correctness proof (semantic preservation) nicely exploits the new features of the CompCert v2 memory model. Namely, the proof shows that the contents of const global variables are identical in the initial memory state and in the memory state at any point of the program execution. Indeed, a successful store
operation performed by the program cannot change the contents of a memory block attached to a const global variables, because 1- such a memory block has maximal permission Readable (at most) in the initial memory state; 2- maximal permissions over already-allocated blocks can only decrease during execution; and 3- a successful store requires Writable current permissions over the locations it modifies.

Besides sporting a nice proof of semantic preservation, constant propagation of const global variables noticeably improves the quality of the assembly code produced by CompCert in some cases. One example that we observed is C code automatically generated from Scade, where the C code generator puts many numerical constants in const global variables rather than naming them with macros.

6 Conclusions and perspectives

Version 2 of the CompCert memory model enables the semantics of the source and intermediate languages of CompCert to describe the memory behavior of programs with increased precision, while preserving all the properties of memory operations that CompCert’s correctness proof relies on. This increase in precision translates into two improvements:

- More of the popular, low-level, non-standard-conformant C programming idioms, such as bit-level manipulations of in-memory representations of integers and floats, can be given well-defined semantics and, therefore, be proved correct with respect to their high-level specifications, but also guaranteed to be compiled by CompCert in a semantics-preserving manner.
- More of the serious C undefined behaviors, such as modifying a string literal, can be captured as errors by the CompCert formal semantics, enabling the CompCert compiler to perform more aggressive optimizations and an hypothetical verification tool based on CompCert’s semantics to guarantee the absence of such errors.

The main limitation that remains CompCert’s memory model is its inability to model byte-level access to pointer values, as can happen in block copy operations, for instance. We argued that this limitation seems to be of low practical importance. Nonetheless, we see two ways to lift this limitation:

- The first approach is fairly ad-hoc and consists in extending CompCert’s type of values with a fifth case, $\text{Vptr\_fragment}(b, i, n)$, abstractly denoting the $n$-th byte of the in-memory representation of pointer $\text{Vptr}(b, i)$. Byte-sized load and store operations would translate between the $\text{Vptr\_fragment}(b, i, n)$ value and the $\text{Pointer}(b, i, n)$ mem value without loss of information. Most if not all arithmetic operations would be undefined over values of the $\text{Vptr\_fragment}$ kind. This is the minimal extension that would give semantics to the $\text{memcpy}$ example.
- The second approach is much more radical: replace CompCert’s current “value” type (a discriminated union of integer, float, pointer and undefined values) by the type list memval of lists of byte-level, in-memory representations of values. This is the approach followed by Norrish in his Cholera formal semantics for the C language [13]; in Cholera, r-value expressions evaluate (conceptually) to their byte-level, in-memory representations. In this approach, encoding and decoding integer/float/pointer values to and from lists of bytes is no longer performed at load/store time, but rather when an arithmetic or logical operation is performed. This is a major departure from the approach followed in CompCert so far.

Finally, the introduction of fine-grained permissions in the memory model is a first step towards extending CompCert to shared-memory, data-race-free concurrency. Further steps in this di-
rection include re-engineering the operational semantics of CompCert’s languages around the “oracle” model of Dockins and Appel [2].

Acknowledgments

We thank Pascal Cuq, Rob Dockins and Alexandre Pilkiewicz for their suggestions and feedback on the design of the v2 memory model and its uses in the CompCert semantics and correctness proofs.
